

Introduction to linear regression

The Human Freedom Index is a report that attempts to summarize the idea of “freedom” through a bunch of different variables for many countries around the globe. It serves as a rough objective measure for the relationships between the different types of freedom - whether it’s political, religious, economical or personal freedom - and other social and economic circumstances. The Human Freedom Index is an annually co-published report by the Cato Institute, the Fraser Institute, and the Liberales Institut at the Friedrich Naumann Foundation for Freedom.

In this lab, you’ll be analyzing data from Human Freedom Index reports from 2008-2016. Your aim will be to summarize a few of the relationships within the data both graphically and numerically in order to find which variables can help tell a story about freedom.

Getting Started

Load packages

In this lab, you will explore and visualize the data using the **tidyverse** suite of packages. The data can be found in the companion package for OpenIntro resources, **openintro**.

Let’s load the packages.

```
library(tidyverse)
library(openintro)
data('hfi', package='openintro')
```

The data

The data we’re working with is in the openintro package and it’s called **hfi**, short for Human Freedom Index.

1. What are the dimensions of the dataset?

Insert your answer here

```
#not using glimpse() because there are a lot of columns and don't want so much information
dim(hfi)
```

```
## [1] 1458 123
```

There are 1458 rows and 123 columns.

2. What type of plot would you use to display the relationship between the personal freedom score, **pf_score**, and one of the other numerical variables? Plot this relationship using the variable **pf_expression_control** as the predictor. Does the relationship look linear? If you knew a country’s **pf_expression_control**, or its score out of 10, with 0 being the most, of political pressures and controls on media content, would you be comfortable using a linear model to predict the personal freedom score?

Insert your answer here

```
ggplot(hfi, aes(x=pf_score, y=pf_expression_control)) +  
  geom_point() +  
  theme_minimal()
```

The appropriate plot would be a scatterplot. There does seem to be a linear relationship between the variable sand I therefore would be comfortable using a linear model to predict the personal freedom score using the political pressure scores as a predictive variable.

If the relationship looks linear, we can quantify the strength of the relationship with the correlation coefficient.

```
hfi %>%  
  summarise(cor(pf_expression_control, pf_score, use = "complete.obs"))  
  
## # A tibble: 1 x 1  
##   'cor(pf_expression_control, pf_score, use = "complete.obs")'  
##                                     <dbl>  
## 1                                     0.796
```

Here, we set the use argument to “complete.obs” since there are some observations of NA.

Sum of squared residuals

In this section, you will use an interactive function to investigate what we mean by “sum of squared residuals”. You will need to run this function in your console, not in your markdown document. Running the function also requires that the hfi dataset is loaded in your environment.

Think back to the way that we described the distribution of a single variable. Recall that we discussed characteristics such as center, spread, and shape. It's also useful to be able to describe the relationship of two numerical variables, such as `pf_expression_control` and `pf_score` above.

3. Looking at your plot from the previous exercise, describe the relationship between these two variables. Make sure to discuss the form, direction, and strength of the relationship as well as any unusual observations.

Insert your answer here *The plot shows that the relationship looks positively linear. By using the above code to calculate the probability, we can see the correlation is fairly strong at 0.8. This can also be seen in the scatterplot.*

Just as you've used the mean and standard deviation to summarize a single variable, you can summarize the relationship between these two variables by finding the line that best follows their association. Use the following interactive function to select the line that you think does the best job of going through the cloud of points.

```
# This will only work interactively (i.e. will not show in the knitted document)
hfi <- hfi %>% filter(complete.cases(pf_expression_control, pf_score))
DATA606::plot_ss(x = hfi$pf_expression_control, y = hfi$pf_score)
```

After running this command, you'll be prompted to click two points on the plot to define a line. Once you've done that, the line you specified will be shown in black and the residuals in blue. Note that there are 30 residuals, one for each of the 30 observations. Recall that the residuals are the difference between the observed values and the values predicted by the line:

$$e_i = y_i - \hat{y}_i$$

The most common way to do linear regression is to select the line that minimizes the sum of squared residuals. To visualize the squared residuals, you can rerun the plot command and add the argument `showSquares = TRUE`.

```
DATA606::plot_ss(x = hfi$pf_expression_control, y = hfi$pf_score, showSquares = TRUE)
```

Note that the output from the `plot_ss` function provides you with the slope and intercept of your line as well as the sum of squares.

4. Using `plot_ss`, choose a line that does a good job of minimizing the sum of squares. Run the function several times. What was the smallest sum of squares that you got? How does it compare to your neighbors?

Insert your answer here *After running the function several times, the smallest sum of residuals I got was 982. (There was something wrong with my interactive viewer and the line was drawn above the two places I clicked, so I had to estimate based on prior results where to draw the line to get the lowest possible result)*

The linear model

It is rather cumbersome to try to get the correct least squares line, i.e. the line that minimizes the sum of squared residuals, through trial and error. Instead, you can use the `lm` function in R to fit the linear model (a.k.a. regression line).

```
m1 <- lm(pf_score ~ pf_expression_control, data = hfi)
```

The first argument in the function `lm` is a formula that takes the form $y \sim x$. Here it can be read that we want to make a linear model of `pf_score` as a function of `pf_expression_control`. The second argument specifies that R should look in the `hfi` data frame to find the two variables.

The output of `lm` is an object that contains all of the information we need about the linear model that was just fit. We can access this information using the summary function.

```
summary(m1)
```

```
##
## Call:
## lm(formula = pf_score ~ pf_expression_control, data = hfi)
##
## Residuals:
##      Min       1Q   Median       3Q      Max
## -3.8467 -0.5704  0.1452  0.6066  3.2060
##
## Coefficients:
##              Estimate Std. Error t value Pr(>|t|)
## (Intercept)      4.61707    0.05745   80.36  <2e-16 ***
## pf_expression_control 0.49143    0.01006   48.85  <2e-16 ***
## ---
## Signif. codes:  0 '***' 0.001 '**' 0.01 '*' 0.05 '.' 0.1 ' ' 1
##
## Residual standard error: 0.8318 on 1376 degrees of freedom
## (80 observations deleted due to missingness)
## Multiple R-squared:  0.6342, Adjusted R-squared:  0.634
## F-statistic: 2386 on 1 and 1376 DF, p-value: < 2.2e-16
```

Let's consider this output piece by piece. First, the formula used to describe the model is shown at the top. After the formula you find the five-number summary of the residuals. The "Coefficients" table shown next is key; its first column displays the linear model's y-intercept and the coefficient of `pf_expression_control`. With this table, we can write down the least squares regression line for the linear model:

$$\hat{y} = 4.61707 + 0.49143 \times pf_expression_control$$

One last piece of information we will discuss from the summary output is the Multiple R-squared, or more simply, R^2 . The R^2 value represents the proportion of variability in the response variable that is explained by the explanatory variable. For this model, 63.42% of the variability in runs is explained by at-bats.

5. Fit a new model that uses `pf_expression_control` to predict `hf_score`, or the total human freedom score. Using the estimates from the R output, write the equation of the regression line. What does the slope tell us in the context of the relationship between human freedom and the amount of political pressure on media content?

Insert your answer here

```
m2 <- lm(hf_score ~ pf_expression_control, data = hfi)
```

```
summary(m2)
```

```
##
## Call:
## lm(formula = hf_score ~ pf_expression_control, data = hfi)
##
## Residuals:
##      Min       1Q   Median       3Q      Max
## -2.6198 -0.4908  0.1031  0.4703  2.2933
##
## Coefficients:
##              Estimate Std. Error t value Pr(>|t|)
## (Intercept)      5.153687   0.046070  111.87  <2e-16 ***
## pf_expression_control 0.349862   0.008067   43.37  <2e-16 ***
## ---
## Signif. codes:  0 '***' 0.001 '**' 0.01 '*' 0.05 '.' 0.1 ' ' 1
##
## Residual standard error: 0.667 on 1376 degrees of freedom
## (80 observations deleted due to missingness)
## Multiple R-squared:  0.5775, Adjusted R-squared:  0.5772
## F-statistic: 1881 on 1 and 1376 DF, p-value: < 2.2e-16
```

Using the estimates from the above output we can calculate the regression line as :

$$\hat{y} = 5.153687 + 0.349862 \times pf_expression_control$$

The slope of 0.349862 tells us there is a positive correlation, and for every increase of one in the variable `pf_expression_control`, we should expect an increase of 0.349862 in the predicted value of the `hf_score`.

Prediction and prediction errors

Let's create a scatterplot with the least squares line for `m1` laid on top.

```
ggplot(data = hfi, aes(x = pf_expression_control, y = pf_score)) +
  geom_point() +
  stat_smooth(method = "lm", se = FALSE)
```

Here, we are literally adding a layer on top of our plot. `geom_smooth` creates the line by fitting a linear model. It can also show us the standard error `se` associated with our line, but we'll suppress that for now.

This line can be used to predict y at any value of x . When predictions are made for values of x that are beyond the range of the observed data, it is referred to as *extrapolation* and is not usually recommended. However, predictions made within the range of the data are more reliable. They're also used to compute the residuals.

6. If someone saw the least squares regression line and not the actual data, how would they predict a country's personal freedom school for one with a 6.7 rating for `pf_expression_control`? Is this an overestimate or an underestimate, and by how much? In other words, what is the residual for this prediction?

Insert your answer here

```
pf_expression_control_v <- 6.7
pf_score_v <- 4.61707 + 0.49143 * pf_expression_control_v
(pf_score_v)
```

```
## [1] 7.909651
```

```
#there are no 6,7 observed variables so I am expanding the parameters
average_residual <- hfi %>%
  filter(pf_expression_control >= 6.65 & pf_expression_control <= 6.75) %>%
  select(pf_expression_control, pf_score) %>%
```

```
mutate(residual = pf_score - 7.909651) %>%
  summarize(average = mean(residual))

(average_residual)
```

```
## # A tibble: 1 x 1
##   average
##   <dbl>
## 1  0.0967
```

The predicted pf_score for a pf_expression_control of 6.7 would be 7.909651. Since there aren't any datapoints for a pf_score of 6.7, it is hard to know if that is an overestimate or underestimate. The closest datapoints we have are for a pf_expression_control of 6.75, so I calculated the residuals of 6.65-6.75 (in reality this is just 6.75 since there aren't any datapoints at 6.65 either). The average residual for the existing datapoints was 0.0967. So the estimated pf_score was an underestimate by that amount.

Model diagnostics

To assess whether the linear model is reliable, we need to check for (1) linearity, (2) nearly normal residuals, and (3) constant variability.

Linearity: You already checked if the relationship between `pf_score` and 'pf_expression_control' is linear using a scatterplot. We should also verify this condition with a plot of the residuals vs. fitted (predicted) values.

```
ggplot(data = m1, aes(x = .fitted, y = .resid)) +
  geom_point() +
  geom_hline(yintercept = 0, linetype = "dashed") +
  xlab("Fitted values") +
  ylab("Residuals")
```

Notice here that `m1` can also serve as a data set because stored within it are the fitted values (\hat{y}) and the residuals. Also note that we're getting fancy with the code here. After creating the scatterplot on the first layer (first line of code), we overlay a horizontal dashed line at $y = 0$ (to help us check whether residuals are distributed around 0), and we also rename the axis labels to be more informative.

7. Is there any apparent pattern in the residuals plot? What does this indicate about the linearity of the relationship between the two variables?

Insert your answer here

There does not seem to be a pattern to the residuals. They also seem to be fairly normally distributed. Based on those observations, we can fairly confidently say there is a linear relationship between the two variables.

Nearly normal residuals: To check this condition, we can look at a histogram

```
ggplot(data = m1, aes(x = .resid)) +  
  geom_histogram(binwidth = 1.5) +  
  xlab("Residuals")
```

or a normal probability plot of the residuals.

```
ggplot(data = m1, aes(sample = .resid)) +  
  stat_qq()
```

Note that the syntax for making a normal probability plot is a bit different than what you're used to seeing: we set `sample` equal to the residuals instead of `x`, and we set a statistical method `qq`, which stands for “quantile-quantile”, another name commonly used for normal probability plots.

8. Based on the histogram and the normal probability plot, does the nearly normal residuals condition appear to be met?

Insert your answer here

Based on the above plots, the nearly normal residual condition is indeed met.

Constant variability:

9. Based on the residuals vs. fitted plot, does the constant variability condition appear to be met?

Insert your answer here

I believe the constant variability condition is met, but there does seem to be more extreme outliers towards either end of the plot.

More Practice

- Choose another freedom variable and a variable you think would strongly correlate with it.. Produce a scatterplot of the two variables and fit a linear model. At a glance, does there seem to be a linear relationship?

Insert your answer here

```
ggplot(hfi, aes(x=ef_legal_integrity, y=ef_legal_courts)) +  
  geom_point() +  
  theme_minimal() +  
  stat_smooth(method = "lm", se = FALSE)
```

There does seem to be a distinct linear relationship between the integrity of the legal system and having impartial courts.

- How does this relationship compare to the relationship between `pf_expression_control` and `pf_score`? Use the R^2 values from the two model summaries to compare. Does your independent variable seem to predict your dependent one better? Why or why not?

Insert your answer here

```
m3 <- lm(ef_legal_integrity ~ ef_legal_courts, data = hfi)  
summary(m1)
```

```
##  
## Call:  
## lm(formula = pf_score ~ pf_expression_control, data = hfi)  
##  
## Residuals:  
##      Min       1Q   Median       3Q      Max
```

```
## -3.8467 -0.5704 0.1452 0.6066 3.2060
##
## Coefficients:
##              Estimate Std. Error t value Pr(>|t|)
## (Intercept)      4.61707    0.05745   80.36 <2e-16 ***
## pf_expression_control 0.49143    0.01006   48.85 <2e-16 ***
## ---
## Signif. codes:  0 '***' 0.001 '**' 0.01 '*' 0.05 '.' 0.1 ' ' 1
##
## Residual standard error: 0.8318 on 1376 degrees of freedom
## (80 observations deleted due to missingness)
## Multiple R-squared:  0.6342, Adjusted R-squared:  0.634
## F-statistic: 2386 on 1 and 1376 DF, p-value: < 2.2e-16
```

```
summary(m3)
```

```
##
## Call:
## lm(formula = ef_legal_integrity ~ ef_legal_courts, data = hfi)
##
## Residuals:
##      Min       1Q   Median       3Q      Max
## -5.3178 -1.2736 -0.1574  1.4011  5.0323
##
## Coefficients:
##              Estimate Std. Error t value Pr(>|t|)
## (Intercept)      2.46768    0.15231   16.2 <2e-16 ***
## ef_legal_courts  0.83283    0.03228   25.8 <2e-16 ***
## ---
## Signif. codes:  0 '***' 0.001 '**' 0.01 '*' 0.05 '.' 0.1 ' ' 1
##
## Residual standard error: 1.725 on 1179 degrees of freedom
## (277 observations deleted due to missingness)
## Multiple R-squared:  0.3608, Adjusted R-squared:  0.3602
## F-statistic: 665.5 on 1 and 1179 DF, p-value: < 2.2e-16
```

The R^2 value of my model is 0.3608, which means the model accurately fits 36.08% of the datapoints, while the R^2 value of the model comparing the relationship between `pf_expression_control` and `pf_score` is 0.6342, which means it accurately fits 63.42% of the datapoints. This means that the latter model does a much better job predicting the outcome of the dependent variable.

- What's one freedom relationship you were most surprised about and why? Display the model diagnostics for the regression model analyzing this relationship.

Insert your answer here

The below plots clearly show a distinct linear relationship between a country's `hf_score` and its `pf_score`. What surprises me however, was the relatively low R^2 value. The R^2 value is 0.4006 which means this model only accurately captures 40.06% of the observed datapoints which is much lower than I would have predicted.

```
m4 <- lm(pf_score ~ ef_score, data = hfi)

ggplot(data = m4, aes(x = .fitted, y = .resid)) +
```

```
geom_point() +  
geom_hline(yintercept = 0, linetype = "dashed") +  
xlab("Fitted values") +  
ylab("Residuals")
```

```
ggplot(data = m4, aes(x = .resid)) +  
geom_histogram(binwidth = 1.5) +  
xlab("Residuals")
```

```
summary(m4)
```

```
##
## Call:
## lm(formula = pf_score ~ ef_score, data = hfi)
##
## Residuals:
##      Min       1Q   Median       3Q      Max
